An Accessory Muscle of Pectoral Region: A Case Report

ABSTRACT
Among the variations of pectoral muscles, this case appears to be unique in the literature. This was a case of an accessory pectoral muscle which was located between pectoralis major and pectoralis minor muscles, which was discovered during a routine anatomy dissection. The accessory muscle originated from 6th and 7th ribs at costo-chondral junction, which travelled supero-laterally and inserted by fusing with fibres of pectoralis minor. This unusual muscle holds importance for surgeons while they perform dissectomies, in avoiding complications.

Key words: Accessory pectoral muscle, Pectoralis major, Pectoralis minor, Medial pectoral nerve, Costo-chondral junction

CASE REPORT
During the routine dissection of a male cadaver in the Department of Anatomy, Shri B M Patil Medical College Bijapur, India, we found a long ribbon like muscle in right pectoral region, which originated from right 5th and 6th ribs at costo-chondral junction, in between the pectoralis major and pectoralis minor muscles [Table/Fig-1]. From its origin, it travelled above and laterally and inserted by fusing with fibres of pectoralis minor. Pectoralis minor was inserted on medial border and upper surface of coracoid process of scapula. Accessory pectoral muscle was 14 cm long and it was 4 cm broad at its origin. The nerve supply to this muscle was through medial pectoral nerve [Table/Fig-2]. No variations were found with regards to origin and insertion of pectoralis major and minor. This accessory muscle was found only on right side and left side pectoral muscles showed no variations.

DISCUSSION
The variants of pectoralis major include: Absence of the abdominal slip of pectoralis major, variations in the number of costal attachments, decussation of right and left muscles across the sternum and ascension of superficial vertical slips from the lower costal cartilages which are called “sternalis”.

Variants of pectoralis minor include: Separation of muscular slips of pectoralis minor and their variations in number and level eg, like one passes from first rib to coracobrachial process, which is called as pectoralis minimus and costal attachments can be 2nd to 5th ribs, 3rd to 5th ribs or 2nd to 4th ribs [1].

Although variations of pectoral muscles are not uncommon, our case appeared to be unique in that this accessory muscle arose separately from 5th and 6th ribs at costo-chondral junction, on right side and fused with pectoralis minor muscle before its termination. An embryological explanation for this finding: The pectoralis muscle is derived from dorsal limb bud masses which arise from myoblasts that migrate out of the last five cervical and first thoracic myotomes into the developing limb buds during the fifth week of development [2]. The pectoralis muscles assume their final forms through a combination of migration, fusion and apoptosis of muscle cell precursors [3]. It is possible that accessory pectoral muscle is a result of a failure of designated myoblasts in undergoing apoptosis.

Reported cases of variations of pectoral muscles: Most common anomaly of pectoralis major is its complete deficiency, which is described as Poland syndrome, which is characterised by unilateral absence of pectoralis major and cutaneous syndactyly [4]. Paraskevas et al reported bilateral hypoplasia of clavicular head of pectoralis major, which was associated with a vascular anomaly in an anteriorly placed external jugular vein, which was referred to as “atypical Poland’s syndrome” [5]. Philip A Fabrizio et al., noted that “pectoralis quartus” had originated from 5th costal cartilage and that it had inserted into the fascia which overlay the coracobrachialis muscle. He also noted an accessory muscle, which was found just lateral to the pectoralis minor, which had originated from external abdominal oblique muscle and had inserted into coracobrachialis fascia, deep into insertion of pectoralis quartus during customary dissections [6].

Leonard P Seimon reported that “epicostobrachialis” muscle arose from the lateral edge of the pectoralis major muscle and inserted into the medial epicondyle of the humerus during routine dissection of a male cadaver [7]. M Loukas and G South et al., reported a case of a unilateral occurrence of a right sided accessory head of pectoralis muscle...

**CONCLUSION**

May enhance the optimal function of shoulder. Muscle through the supplementation of accessory pectoral muscles is immense [12]. Increased size and origin of the pectoralis minor muscle fibres. Pectoralis minor is commonly used as a landmark during difficulties may be encountered due to presence of these accessory muscles. Accessory pectoral muscles may be mistaken for masses or tumours during CT or MRI scans. During pectoral flap surgeries, complications. Accessory pectoral muscles may be distinctive in the literature. The possible clinical importance of the present case should be discussed, as the knowledge on this is important to anatomists as well as surgeons, for preventing complications during surgery and to benefit from the outcomes of surgery. This case report illustrates a need for reporting such cases and discussing about their clinical importance.

**ACKNOWLEDGEMENT**

Authors acknowledge the immense help which was received from the scholars whose articles were cited and included in references of this manuscript. The authors are also grateful to authors/editors-publishers of all those articles journals and books from where the literature for this article has been reviewed and discussed.
