Multiple Ileal Perforations Following Dilatation and Evacuation for Missed Abortion

SIR,

Miscarriage has traditionally been treated by surgical evacuation, on the assumption that any retained tissue increases the risk of infection and haemorrhage. One of the serious risks of surgical evacuation is uterine perforation (up to 5 in 1000 women) [1]. Over the last decade, the management of abortion has become medical to reduce the life threatening complications associated with surgical techniques. But still medical management is not being followed by every practising obstetrician or surgeon. A 25-year-old married lady presented to our hospital with fever, abdominal pain and vomiting for 2 days following dilatation and evacuation for missed abortion at 8 weeks of gestation at a private hospital. Abdomen was tender and guarding was present. On laparotomy, there was a 5mm perforation on the anterior wall of the uterus near the fundus [Table/Fig-1] and multiple (6) ileal perforations measuring 0.5-1cm each [Table/Fig-2].

Uterine perforation was freshened and approximated with vicryl. Segmental resection and anastomosis of 8 cm of the ileum was performed. Post-operatively she had febrile spikes which subsided on the 4th day; peritoneal fluid aspirate culture showed E.Coli which resolved with appropriate antibiotics. On 10th day post-operation, she was discharged home. She continued to have pain in the abdomen which was managed as acid peptic disease on outpatient basis. She required admission once when she presented to casualty 46 days after discharge from hospital with upper abdominal pain and vomiting and a provisional diagnosis of adhesive intestinal obstruction was made. Her symptoms subsided with conservative treatment. The present day treatment of abortion is medical management [2]. Surgery has a limited role. The aim of the surgical procedure should be to treat an incomplete or missed miscarriage, or retained placental tissue not responsive to timely medical management.
